**ABSTRACT** Geometrical confinement effect in exfoliated sheets of layered materials leads to significant evolution of energy dispersion in mono- to few-layer thickness regime. Molybdenum disulfide (MoS<sub>2</sub>) was recently found to exhibit indirect-to-direct gap transition when the thickness is reduced to a single monolayer. Emerging photoluminescence (PL) from monolayer MoS<sub>2</sub> opens up opportunities for a range of novel optoelectronic applications of the material. Here we report differential reflectance and PL spectra of mono- to few-layer WS<sub>2</sub> and WSe<sub>2</sub> that indicate that the band structure of these materials undergoes similar indirect-to-direct gap transition when thinned to a single monolayer. The transition is evidenced by distinctly enhanced PL peak centered at 630 and 750 nm in monolayer WS<sub>2</sub> and WSe<sub>2</sub>, respectively. Few-layer flakes are found to exhibit comparatively strong indirect gap emission along with direct gap hot electron emission, suggesting high quality of synthetic crystals prepared by a chemical vapor transport method. Fine absorption and emission features and their thickness dependence suggest a strong effect of Se p-orbitals on the d electron band structure as well as interlayer coupling in WSe<sub>2</sub>.

**KEYWORDS:** WS<sub>2</sub> · WSe<sub>2</sub> · 2D crystals · photoluminescence

Atomically thin sheets of molybdenum disulfide (MoS<sub>2</sub>) consisting of a single to a few monolayers were recently found to exhibit a set of unusual properties associated with their two-dimensional (2D) structure and high crystal quality, triggering significant research interest.<sup>1–18</sup> Similar to graphite, MoS<sub>2</sub> crystallizes in a van der Waals layered structure where each layer consists of a slab of S–Mo–S sandwich. Individual monolayers can be mechanically peeled off from a bulk crystal and isolated as a graphene-like 2D crystal.<sup>19</sup> While MoS<sub>2</sub> is traditionally known as a solid-state lubricant and catalyst, its mono- and few-layer crystals hold promise in novel electronic and optoelectronic applications and provides access to fundamental physical phenomena.

Electronically, bulk MoS<sub>2</sub> is an indirect gap semiconductor with the bandgap in the near-infrared frequency range (~1.2 eV).<sup>20</sup> In contrast, monolayer MoS<sub>2</sub> is a direct gap semiconductor with the band gap in the visible frequency range (~1.9 eV).<sup>4,5</sup>

Confinement of carriers in the out-of-plane direction induces gradual increase in the band gap with decreasing thickness.<sup>21</sup> The indirect to direct crossover occurs at the monolayer limit resulting in strong contrast in photoluminescence (PL) efficiency between single and multilayer sheets.<sup>4,5</sup> Remarkable electrical properties of mono- and few-layer MoS<sub>2</sub> are increasingly revealed in its field effect transistor characteristics such as exceptionally large on/off ratio, small subthreshold swing, ultralow off-state energy dissipation, high field effect mobility, and large current carrying capacity.<sup>1–3</sup> Explicit inversion symmetry breaking in monolayers allows valley selective pumping of charges using circularly polarized light.<sup>6–8</sup> High electronic quality of the material coupled with thickness-dependent optical properties, mechanical flexibility,<sup>9</sup> and access to valley degree of freedom highlights some of the distinct characteristics of MoS<sub>2</sub> 2D crystals.<sup>10–18</sup>

Tungsten-based dichalcogenides such as WS<sub>2</sub> and WSe<sub>2</sub> belong to the same family of

layered transition metal dichalcogenides (LTMD) as  $\text{MoS}_2$ .<sup>22</sup> Mechanically exfoliated atomically thin sheets of  $\text{WS}_2$  and  $\text{WSe}_2$  were recently shown to exhibit high in-plane carrier mobility and electrostatic modulation of conductance similar to  $\text{MoS}_2$ .<sup>23,24</sup> Both compounds exhibit trigonal prismatic structure and are indirect gap semiconductors in the bulk form with a bandgap of 1–1.3 eV. The M–M bond length (where M represents a transition metal atom) is nearly identical for  $\text{MoS}_2$  (3.16 Å) and  $\text{WS}_2$  (3.15 Å) while it is slightly larger for  $\text{WSe}_2$  (3.28 Å).<sup>22</sup> Interlayer distance is correspondingly larger for  $\text{WSe}_2$  due to the large Se atoms. General features of the  $\text{WS}_2$  and  $\text{WSe}_2$  band structures are similar to those of  $\text{MoS}_2$  where a direct and indirect gap coexist irrespective of thickness.<sup>25–27</sup> A direct gap exists at the K points of the Brillouin zone between the spin–orbit split valence band and the doubly degenerate conduction band. On the other hand, an indirect gap forms between a local conduction band minimum at a midpoint between  $\Gamma$  and K and the valence band maximum at the  $\Gamma$  point. The primary difference between  $\text{MoX}_2$  (where X represents a chalcogen atom) and  $\text{WX}_2$  is the size of the spin–orbit splitting due to different size of the transition metal atoms.

While  $\text{MoS}_2$  2D crystals have been intensively studied in recent years, reports on mono- and few-layer  $\text{WS}_2$  and  $\text{WSe}_2$  are limited. Here we report differential reflectance and PL spectra of mechanically exfoliated sheets of synthetic 2H- $\text{WS}_2$  and 2H- $\text{WSe}_2$  with thicknesses ranging between 1 and 5 layers. The excitonic absorption and emission bands were found to gradually blueshift with decreasing number of layers due to geometrical confinement of excitons. Strong enhancement in PL efficiency is observed in the monolayers indicating that they are direct gap semiconductors in agreement with the recent experimental findings<sup>28,29</sup> and calculations.<sup>25,26</sup> We show that interlayer coupling effects can be investigated by studying fine absorption and emission features and their dependence on flake thickness. We further demonstrate that the PL emission efficiency of monolayers is higher for synthetic  $\text{WS}_2$  and  $\text{WSe}_2$  crystals compared to natural  $\text{MoS}_2$  crystals.

## RESULTS/DISCUSSION

Mechanically exfoliated flakes of  $\text{WS}_2$  and  $\text{WSe}_2$  were deposited on quartz or  $\text{SiO}_2/\text{Si}$  substrates and their thickness was verified by atomic force microscopy (AFM) and optical contrast (see Supporting Information for AFM images).<sup>30</sup> These samples were chemically stable over 3 months in ambient conditions and showed no obvious sign of degradation according to our Raman analysis.<sup>31</sup> For atomically thin layers supported by a transparent substrate, differential reflectance provides an effective measure of absorbance. The fractional change in reflectance  $\delta R$  for a thin layer sample relative to the reflectance of a dielectric

**Figure 1.** Differential reflectance spectra of mechanically exfoliated (a) 2H- $\text{WS}_2$  and (b) 2H- $\text{WSe}_2$  flakes consisting of 1–5 layers. The peaks are labeled according to the convention proposed by Wilson and Yoffe.<sup>22</sup>

substrate with refractive index of  $n_{\text{subs}}$  is related to the absorbance ( $A$ ) of the material by<sup>32</sup>

$$\delta R(\lambda) = \frac{4}{n_{\text{subs}}^2 - 1} A(\lambda) \quad (1)$$

We assume  $n_{\text{subs}}$  to be wavelength independent for the spectral range investigated in this study. Figure 1 panels a and b show the differential reflectance spectra of 1–5 layer  $\text{WS}_2$  and  $\text{WSe}_2$ , respectively. Absorption features for bulk crystals have been previously studied by Beal *et al.*<sup>33</sup> and Bromley *et al.*<sup>34</sup> General features of the peaks are in good agreement with the previously reported results. All peaks exhibit a gradual but distinct blueshift with decreasing flake thickness similar to early findings.<sup>35</sup> Excitonic absorption peaks A and B which arise from direct gap transitions at the K point are found, respectively, around 625 and 550 nm for  $\text{WS}_2$  and around 760 and 600 nm for  $\text{WSe}_2$  in agreement with the previous studies on bulk layers.<sup>33,34</sup> The energy difference between the A and B peaks, which is an indication of the strength of spin–orbit interaction, is approximately 400 meV for both  $\text{WS}_2$  and  $\text{WSe}_2$  in reasonable agreement with the calculations.<sup>36</sup>

**Figure 2.** (a,b) Normalized PL spectra of mechanically exfoliated (a) 2H-WS<sub>2</sub> and (b) 2H-WSe<sub>2</sub> flakes consisting of 1–5 layers. Peak I is an indirect gap emission. Weak hot electron peaks A' and B are magnified and shown as dashed lines for clarity. These hot electron peaks are typically 100 to 1000 times weaker than the band edge emission peaks. The total emission intensity becomes significantly weaker with increasing number of layers. (c,d) Relative decay in the PL QY with the number of layers for (c) WS<sub>2</sub> and (d) WSe<sub>2</sub>. The values are relative to the PL QY of a monolayer flake as discussed in the text. The plots are shown for A and I peaks and their sum (A+I).

It should be noted that this value is significantly larger than the  $\sim 160$  meV splitting observed for MoS<sub>2</sub>.<sup>4,5</sup>

For WS<sub>2</sub>, an additional peak, previously labeled as C, is observed around 450 nm. This peak arises from optical transitions between the density of states peaks in the valence and conduction bands.<sup>37</sup> The WSe<sub>2</sub> spectra show more additional features due to greater overlap of Se p orbitals with W d orbitals as well as those of adjacent layers.<sup>33,34</sup> The absorption peaks A' and B' are believed to be excitonic in nature and arise from the splitting of the ground and excited states of A and B transitions, respectively, due to inter- and intralayer perturbation to the d electron band by the Se p orbitals.<sup>33,34</sup> The energy separation between A' and B' peaks are found to be  $\sim 400$  meV consistent with this picture. It may be noted that the presence of A' and B' peaks in monolayer WSe<sub>2</sub> suggests that A-A' and B-B' splitting are mainly due to intralayer effects.

In contrast to absorption, PL spectra show remarkable dependence on flake thickness for both materials as shown in Figure 2a,b. The most notable change is the sudden increase in emission intensity when the flake is thinned to a monolayer (Figure 2c,d). Both monolayer WS<sub>2</sub> and WSe<sub>2</sub> flakes exhibit strong emission at the energy corresponding to A excitonic absorption, whereas the emission intensity is dramatically reduced for multilayer flakes. While an accurate measurement of the PL quantum yield (QY) is challenging, relative changes in QY between different samples can be evaluated based on the PL and absorption spectra. Since the integrated PL intensity  $I$  is proportional to the product of  $\alpha(\lambda_{\text{exc}})$  and QY, where  $\alpha(\lambda_{\text{exc}})$  is the

absorption coefficient at the excitation wavelength  $\lambda_{\text{exc}}$ , we can evaluate the relative magnitude of QY by comparing  $I/\alpha(\lambda_{\text{exc}})$ . Figure 2 panels c and d show relative decrease in PL QY with respect to monolayer flakes. For WS<sub>2</sub>, PL QY drops by more than 100 folds when the thickness is increased from monolayer to bilayer and gradually diminishes with a further increase in thickness. A similar jump in PL QY was observed for WSe<sub>2</sub> although the changes between monolayer and bilayer flakes is less pronounced.

For A excitonic emission from monolayer WS<sub>2</sub> and WSe<sub>2</sub>, Stokes shift was typically around 20 and 3 meV and the corresponding full width at half-maximum (fwhm) for these peaks was 75 and 26 meV, respectively (see Supporting Information for details). It is known that for quantum well structures, Stokes shift and emission line width are an indication of interfacial quality.<sup>38</sup> A recent study showed that the size of the Stokes shift in monolayer MoS<sub>2</sub> increases with doping concentration.<sup>39</sup> The narrow emission line, whose fwhm is comparable to thermal energy at room temperature, along with the small Stokes shift indicates the high quality of our WSe<sub>2</sub> samples.

In addition to the A exciton peak, another peak at a longer wavelength was observed for multilayer samples of both materials. This is attributed to indirect band gap emission involving a conduction band minimum at a midpoint between K and  $\Gamma$  points and valence band maximum at the  $\Gamma$  point. Calculations show that for WSe<sub>2</sub> bilayers, the indirect gap emission involves a valence band maximum at the  $\kappa$  point which is nearly degenerate with the band maximum at the

**Figure 3.** Absorption (gray) and PL (color-coded) peak energies of  $\text{WS}_2$  and  $\text{WSe}_2$  flakes as a function of the number of layers. The letters I, A, B, A', B', and C refer to the peaks labeled in Figures 1 and 2.

$\Gamma$  point.<sup>26,40</sup> It should be noted that the indirect gap emission peak is virtually absent in the monolayer emission spectra, indicating that both  $\text{WS}_2$  and  $\text{WSe}_2$  become a direct gap semiconductor when they are thinned to a single monolayer. This observation along with the distinctly strong emission from monolayers is in good agreement with the calculated<sup>25–27</sup> results as well as the recent experimental findings.<sup>28</sup>

We observed that the decay in emission intensity with increasing thickness is more moderate for  $\text{WSe}_2$  compared to  $\text{WS}_2$ . This is attributed to the small difference between the direct and indirect emission energies. For bulk  $\text{WSe}_2$ , the energy difference between the  $\Gamma$  and K points of the valence band was previously measured by photoemission spectroscopy to be <80 meV.<sup>41,42</sup> Theoretical calculations also yield similar results.<sup>26,40</sup> For bilayer  $\text{WSe}_2$ , the difference between the direct and indirect gaps is a measure of the energy separation between the conduction minimum at the K point and at a midpoint between  $\Gamma$  and K points. On the basis of our PL results we find this energy separation in bilayer  $\text{WSe}_2$  to be about 70 meV. In comparison, the difference between the indirect and direct band gaps in bilayer  $\text{WS}_2$  is much greater (~300 meV). Because the population of hot electrons that transiently occupy the direct band edge at the K point is higher in bilayer  $\text{WSe}_2$  than in bilayer  $\text{WS}_2$  due to the smaller energy difference between its direct and indirect gaps, its A exciton hot electron emission is more pronounced. A similar scenario was recently reported for few-layer  $\text{MoSe}_2$ .<sup>43</sup>

For multilayer samples, the indirect gap emission intensity is comparable to or higher than that of hot electron emission from A excitons. We compared the indirect gap emission intensity of natural  $\text{MoS}_2$  and our CVT-grown  $\text{WX}_2$  multilayers and found that the emission intensity was consistently higher for the synthetic samples. Radiative recombination across an indirect

**Figure 4.** Bright field optical (left panels) and corresponding fluorescence (right panels) images of mechanically exfoliated (a)  $\text{WS}_2$  and (b)  $\text{WSe}_2$  flakes on a quartz substrate. The scale bar is 5  $\mu\text{m}$ . The fluorescence images were obtained with excitation wavelength of 510–550 nm. Due to low efficiency of the CCD camera in the NIR range, the fluorescence image contrast is artificially enhanced for  $\text{WSe}_2$ . The original image can be found in the Supporting Information.

gap is a slow process requiring phonons with an appropriate momentum. In the presence of defects acting as nonradiative traps, nonradiative decay will dominate and suppress the PL QY. Observation of comparatively strong indirect gap emission therefore provides further evidence that our CVT-grown samples are of high quality.

Figure 3 shows absorption and PL peak energies as a function of the number of layers. The A and B exciton peak positions are only weakly dependent on the flake thickness while the indirect band gap quickly decreases with increasing thickness. The robust direct gap at the K point (i.e. weakly thickness-dependent A and B transition energies) is attributed to the absence of dispersion in the out-of-plane direction (or large effective mass in the out-of-plane direction). On the other hand, out-of-plane dispersion around the  $\Gamma$  point (i.e. along the  $\Gamma$ –A line) and a midpoint between the  $\Gamma$ –K line is greater and results in thickness dependent indirect gap. Therefore, a large shift in absorption and emission peaks with flake thickness is an indication of out-of-plane dispersion or interlayer coupling of the electronic states involved in the transition. The energy of A, B, and C peaks in  $\text{WS}_2$  and A and B peaks in  $\text{WSe}_2$  are weakly dependent on the flake thickness indicating that the electrons localized within the plane of X–W–X sandwich are responsible for these optical transitions. For  $\text{WSe}_2$ , the shift in peaks A' and B' are more pronounced compared to that of peaks A and B suggesting that the electronic states associated with these optical transitions are more extended in the out-of-plane direction.

**Figure 5.** Relative integrated PL intensity of  $\text{WS}_2$  and  $\text{WSe}_2$  monolayers and  $\text{WSe}_2$  bilayer with respect to that of a  $\text{MoS}_2$  monolayer plotted against absorbance at the excitation wavelength of 473 nm. The PL emission spectra were integrated over 520–950 nm. Absorbance is obtained from differential reflectance of samples on quartz based on eq 1. The absorbance of  $\text{MoS}_2$  is obtained from ref 5. Note that the comparison is made between exfoliated samples from synthetic (*i.e.*, CVT-grown)  $\text{WS}_2/\text{WSe}_2$  and natural  $\text{MoS}_2$  (SPI supplies) crystals.

Photoluminescence from monolayer flakes was sufficiently strong to be imaged under fluorescence microscope. Figure 4 shows bright field optical microscope images and corresponding fluorescence images of exfoliated  $\text{WS}_2$  and  $\text{WSe}_2$  flakes on quartz substrates. The fluorescence images clearly show red luminescence from the monolayer regions consistent with the PL spectrum. Emission intensity from the adjacent bilayer regions is not sufficiently strong to be imaged under the exposure condition used. The emission intensity is uniform across the monolayer region, verifying that the PL is not due to anomalies arising from flake edges. Similar fluorescence images were obtained for samples deposited on  $\text{SiO}_2/\text{Si}$  substrates (see Supporting Information). These results demonstrate that fluorescence imaging offers a powerful tool to quickly identifying monolayers.

Ideal direct band gap semiconductors are expected to exhibit high PL QY. However, the PL QY of the  $\text{MoS}_2$  monolayer was previously found to be extremely low ( $4 \times 10^{-3}$ ).<sup>5</sup> The origin of the low QY is yet to be

understood. Unintentional doping in the natural crystals with an estimated concentration of  $\sim 10^{12} \text{ cm}^{-2}$ <sup>1,6,18</sup> may play a role in suppressing exciton formation and/or its radiative recombination.<sup>44,45</sup> Figure 5 shows a relative comparison of the emission intensity from exfoliated  $\text{MoS}_2$ ,  $\text{WS}_2$  and  $\text{WSe}_2$ . The emission intensity of our monolayer  $\text{WS}_2$  and  $\text{WSe}_2$  is 20 to 40 times higher than that of monolayer  $\text{MoS}_2$  exfoliated from a natural crystal. The emission from bilayer  $\text{WSe}_2$  is also more efficient in comparison to monolayer  $\text{MoS}_2$ . The differences in PL QY may arise due to various intrinsic and extrinsic factors. We suspect that the observed differences in PL QY mainly arise from unintentional doping in our samples. Further studies are required to elucidate the origin of the variations in PL QY reported here.

## CONCLUSIONS

In summary, we studied the evolution of electronic structure in atomically thin  $\text{WS}_2$  and  $\text{WSe}_2$  sheets using differential reflectance and PL spectroscopy. Our results demonstrate that indirect-to-direct gap crossover occurs in these materials when they are thinned to a single monolayer similar to the case of  $\text{MoS}_2$ . Due to direct gap excitonic recombination, strongly enhanced PL centered at 630 and 750 nm is observed from monolayer  $\text{WS}_2$  and  $\text{WSe}_2$ , respectively. The emission from monolayers is 100 to 1000 times stronger than from the bulk materials. The high quality of our CVT-grown samples is suggested by the distinct indirect gap emission, small Stokes shift, and narrow emission line width. Enhanced interlayer coupling in  $\text{WSe}_2$  is suggested by the pronounced thickness-dependent shift of  $A'$  and  $B'$  absorption and emission peaks.

Our findings demonstrate the unique variations in the optical properties of 2D semiconducting crystals belonging to the family of group 6 LTMDs. Structural similarities of these materials allows fabrication of coherent artificial crystals consisting of electronically dissimilar layers.<sup>46–48</sup> Monolayer  $\text{WS}_2$  and  $\text{WSe}_2$  with direct band gap in the visible and NIR frequency ranges, respectively, are novel building blocks for realizing unique heterostructures with tailored optoelectronic, electrocatalytic, and photocatalytic functionalities.<sup>49</sup>

## METHOD

Synthetic crystals of 2H- $\text{WS}_2$  and 2H- $\text{WSe}_2$  were grown by the chemical vapor transport (CVT) method using iodine as the transport agent. Commercial natural 2H- $\text{MoS}_2$  (SPI Supplies) was studied for comparison. The crystals were mechanically exfoliated and deposited on quartz and  $\text{SiO}_2/\text{Si}$  substrates for subsequent characterizations. Regions of the sample containing mono- and few-layer sheets were first identified under optical microscope and the number of layers was verified by atomic force microscope (AFM) and optical contrast. Differential reflectance measurements were performed using a Jobin-Yvon HR800 micro-Raman system equipped with a liquid nitrogen cooled charge-coupled detector. A tungsten-halogen lamp was

used as a light source. Differential reflectance is defined as  $1 - R_S/R_Q$ , where  $R_S$  and  $R_Q$  are the reflected light intensities from the quartz substrate with and without  $\text{WS}_2/\text{WSe}_2$  flake samples, respectively. The light illuminating the sample was focused down to a  $1 \mu\text{m}$  spot using a small confocal hole. The spectra acquisition time was 15 s. The intensity of the light incident on the sample was kept low ( $<1 \text{ mW}$ ) in order to avoid sample damage. Photoluminescence spectra were obtained in a back scattering geometry with a 473 nm excitation laser at intensities less than  $150 \mu\text{W}$ . The fluorescence images were obtained with an Olympus fluorescence microscope equipped with a Mercury lamp as the excitation light source.
